Abstract

This work presents a versatile method for simultaneous multielemental analysis using detection with photodiode arrays and multivariate calibration techniques. A multidetection system based on an array of 1 024 photodiodes was built and adapted to a commercial plasma emission scanning spectrometer. Spectral data were acquired at low resolution, allowing simultaneous monitoring of a broad spectral range and resulting in very informative but considerably overlapped spectra. Partial least squares and principal component regressions were employed to minimize overlapping problems. A numerical procedure for window selection was also developed.

The new method was applied to the simultaneous determination of manganese, molybdenum, nickel, chromium and iron in steel samples, resulting in average relative prediction errors of 2.1% for Mn, 3.4% for Mo, 0.6% for Cr, 1.5% for Ni and 0.8% for Fe. These errors are comparable to those observed with conventional scanning detection systems and separate univariate calibrations, but the new method allows simultaneous determination of the five elements, with data acquisition significantly faster than in scanning instruments. © 1997 Elsevier Science B.V.

1. Introduction

Inductively coupled plasma atomic emission spectrometry (ICP-AES) is well-established as a powerful technique for multielemental analysis [1]. The high temperature of the source minimizes matrix effects and produces adequate sensitivity for most metals and some non-metals, in concentrations ranging from percent to ppb. Also, since many intense emission lines occur for almost all elements present in a given sample, ICP-AES is essentially a simultaneous multicomponent analytical technique. Many conventional detection systems, however, are not optimized for full exploitation of the enormous amount of information produced by an ICP source.

Most of the early commercially available instruments employ detection systems based on photomultiplier tubes (PMT) [2]. The usual designs either couple one PMT with a scanning monochromator or employ a polychromator with several fixed exit slits and photomultipliers, resulting in the so-called direct-reading spectrometers [3]. Scanning
